Research Article

Ophthalmology

Mutations in the cellular retinaldehyde-binding protein (CRALBP, encoded by *RLBP1*) can lead to severe cone photoreceptor-mediated vision loss in patients. It is not known how CRALBP supports cone function or how altered CRALBP leads to cone dysfunction. Here, we determined that deletion of *Rlbp1* in mice impairs the retinal visual cycle. Mice lacking CRALBP exhibited M-opsin mislocalization, M-cone loss, and impaired cone-driven visual behavior and light responses. Additionally, M-cone dark adaptation was largely suppressed in CRALBP-deficient animals. While rearing CRALBP-deficient mice in the dark prevented the deterioration of cone function, it did not rescue cone dark adaptation. Adeno-associated virus-mediated restoration of CRALBP expression specifically in Müller cells, but not retinal pigment epithelial (RPE) cells, rescued the retinal visual cycle and M-cone sensitivity in knockout mice. Our results identify Müller cell CRALBP as a key component of the retinal visual cycle and demonstrate that this pathway is important for maintaining normal cone-driven vision and accelerating cone dark adaptation.

Mutations in the cellular retinaldehyde-binding protein (CRALBP, encoded by *RLBP1*) can lead to severe cone photoreceptor-mediated vision loss in patients. It is not known how CRALBP supports cone function or how altered CRALBP leads to cone dysfunction. Here, we determined that deletion of *Rlbp1* in mice impairs the retinal visual cycle. Mice lacking CRALBP exhibited M-opsin mislocalization, M-cone loss, and impaired cone-driven visual behavior and light responses. Additionally, M-cone dark adaptation was largely suppressed in CRALBP-deficient animals. While rearing CRALBP-deficient mice in the dark prevented the deterioration of cone function, it did not rescue cone dark adaptation. Adeno-associated virus-mediated restoration of CRALBP expression specifically in Müller cells, but not retinal pigment epithelial (RPE) cells, rescued the retinal visual cycle and M-cone sensitivity in knockout mice. Our results identify Müller cell CRALBP as a key component of the retinal visual cycle and demonstrate that this pathway is important for maintaining normal cone-driven vision and accelerating cone dark adaptation.

Introduction

Photoactivation of a visual pigment molecule in vertebrate rod and cone photoreceptors rapidly triggers a light response and concomitantly renders the activated pigment unable to detect a subsequent photon of light. Regeneration of the visual pigment back to the ground state requires recycling of its chromophore from the “bleached” all-*trans* retinal to the light-sensitive 11-*cis* retinal. This process, known as the visual cycle, requires export of the all-*trans* chromophore out of the photoreceptors and its conversion to the 11-*cis* form in retinal pigment epithelial (RPE) cells (for both rods and cones) or in retinal Müller glia (for cones only). The 11-*cis* chromophore is then imported back into photoreceptors, where it combines with a molecule of free opsin to regenerate the visual pigment (1, 2). The cone-specific visual cycle (3) has been suggested to enable cones, but not rods, to quickly recover from bright light exposure and to function over a wide range of light intensities (4–6). While an active area of research (7, 8), to date, none of the putative molecular components in this pathway have been shown to actually affect mammalian cone function, casting doubt on the significance of this pathway.

Cellular retinaldehyde-binding protein (CRALBP) is a retinoid-binding protein expressed in RPE and Müller glia and believed to be involved in the retinal visual cycle (1). CRALBP is a 36-kDa water-soluble protein with 2 conformational states facilitating the intracellular transport of hydrophobic 11-*cis* retinoids (9). In zebrafish, 2 distinct orthologs, *cralbp a* and *cralbp b*, are expressed in RPE and Müller cells, respectively (10, 11). Notably, knockdown

of either of the 2 isoforms leads to decreased cone-driven electroretinographic (ERG) responses (10), suggesting a role of Müller cell-expressed CRALBP in zebrafish cone function (see also ref. 12). In mammals, CRALBP is encoded by a single gene, *Rlbp1*, expressed in both RPE and Müller cells. Mutations in human *RLBP1* cause several autosomal recessive retinal diseases, such as autosomal recessive retinitis pigmentosa (13), Bothnia dystrophy (14–16), retinitis punctata albescens (17), fundus albipunctatus (18, 19), and Newfoundland rod-cone dystrophy (20). These visual disorders are characterized by early-onset night blindness and may be followed by functional defects in the macular region (21). CRALBP is required for the proper function of the RPE visual cycle and for the timely recovery of mammalian rod and cone ERG responses (22). However, the role of Müller cell-expressed CRALBP in the mammalian retinal visual cycle is unknown. It is also not clear whether CRALBP in RPE, Müller cells, or both is required for the normal function of mammalian cones. Here, we used behavioral and electrophysiological assays in *Rlbp1*^{-/-} mice to examine the overall effect of CRALBP deletion on M-cone function. We also used molecular tools to explore the mechanism by which the lack of CRALBP causes cone function deterioration. We then used adeno-associated virus-mediated (AAV-mediated) gene transfer to selectively restore CRALBP in RPE or Müller cells and examine the distinct roles of the 2 visual cycles in supporting mammalian M-cone function.

Results

The deletion of CRALBP suppresses mammalian cone visual function. In addition to causing well-documented rod-driven scotopic visual disorders (15, 17), mutations in CRALBP also disrupt cone-driven photopic vision in humans (13, 16, 20). It is believed that

Figure 1. Deletion of CRALBP reduces photopic in vivo ERG-response amplitude and sensitivity. (A) Representative in vivo cone ERG responses from control (black traces), *Rlbp1*^{-/-} (red traces), and *Rlbp1*^{+/+} (blue traces) mice. Test flash intensities increased from 2.27×10^{-2} $\text{cd} \times \text{s}/\text{m}^2$ (bottom traces) to $697 \text{ cd} \times \text{s}/\text{m}^2$ (top traces) in steps of approximately 0.5 log units. (B) Ensemble-averaged cone b-wave intensity-response curves for control ($n = 10$), *Rlbp1*^{-/-} ($n = 12$), and *Rlbp1*^{+/+} ($n = 10$) mice. (C) Cone b-wave intensity-response curves for control mice aged 6–7 weeks (black squares, $n = 8$) and 13–16 weeks (white squares, $n = 10$). (D) Cone b-wave intensity-response curves for *Rlbp1*^{-/-} mice aged 6–7 weeks (red circles, $n = 6$) and 13–16 weeks (white circles, $n = 6$). Insets in B–D show the corresponding normalized (r/r_{max}) intensity-response curves. Results represent the mean \pm SEM.

the pathophysiology for both rods and cones is based on inefficient chromophore recycling (13, 14). However, the exact mechanisms of cone dysfunction in CRALBP-related diseases and the relative contributions of the RPE visual cycle and the retinal visual cycle to cone dark adaptation are unknown. To address these questions, we first examined how the deletion of CRALBP affects the cone-driven photopic visual performance of CRALBP-knockout mice by optomotor response behavioral tests. All functional experiments were performed with knockout mice lacking the rod transducin α subunit (*Gnat1*^{-/-}). This facilitated the isolation of cone function by ablating rod photoresponses while preserving normal retina morphology and cone function (6, 23). The experiments were performed with LCD monitor white light, which would be expected to selectively activate mouse M-cones (peak absorption at 508 nm) but not S-cones (peak absorption at 360 nm) (24). We found that the background light intensity required to achieve half-maximal cone-driven contrast sensitivity in 6-week-old *Rlbp1*^{-/-} mice was approximately 10-fold higher than that required for controls (-0.4 and $-1.3 \text{ log cd} \times \text{s}/\text{m}^2$, respectively). Thus, the absence of CRALBP caused a substantial desensitization of cone-driven vision.

We then asked whether the vision loss observed at a behavioral level was caused by the deterioration of cone function in the absence of CRALBP. We conducted in vivo ERG recordings to examine the dark-adapted cone b-wave responses of 6- to 13-week-old *Rlbp1*^{-/-} mice. We used 530-nm LED flashes to selectively excite M-cones (24) up to the system's $25 \text{ cd} \times \text{s}/\text{m}^2$ intensity limit and Xenon flash for higher intensities. We observed a significant 40% ($P < 10^{-4}$) decrease in the maximal M-cone b-wave amplitude in *Rlbp1*^{-/-} mice compared with that in both *Rlbp1*^{+/+} (control) and *Rlbp1*^{-/-} mice (Figure 1, A and B). In addition, we found a dramatic

20-fold decrease in photopic sensitivity, as measured by the corresponding increase in $I_{1/2}$ (the flash intensity required to achieve a half-maximal response) of the *Rlbp1*^{-/-} cone b-wave responses (Figure 1B). Surprisingly, light sensitivity in the absence of CRALBP was diminished to such an extent that even the brightest light stimulus of the ERG system ($697 \text{ cd} \times \text{s}/\text{m}^2$, Xenon flash) could not generate a saturated photopic b-wave response (Figure 1B, red circles). In contrast, light sensitivity in *Rlbp1*^{+/+} mice was comparable to that in control mice (Figure 1B, blue triangles, inset).

In the course of these recordings, we noticed that the older *Rlbp1*^{-/-} mice had smaller cone b-wave amplitudes than did the young adult mice. We compared the ERG b-wave responses from 6- to 7-week-old and 13- to 16-week-old mice to examine the long-term effect of CRALBP knockout on mouse photopic vision. In control animals, cone b-wave amplitude showed an approximately 10% (NS) reduction with age (Figure 1C). In contrast, the cone b-wave amplitude of *Rlbp1*^{-/-} mice decreased by nearly 50% ($P < 0.001$) over the same 2-month period (Figure 1D). The light sensitivity, as estimated from the $I_{1/2}$ of the respective normalized intensity-response curves, remained unchanged for both groups within the 2 months of aging (Figure 1, C and D, insets). Thus, the deletion of CRALBP caused a dramatic and progressive reduction in cone-driven visual performance.

The deletion of CRALBP desensitizes mammalian cones and lowers their phototransduction amplification. The reduced photopic b-wave amplitude and sensitivity of CRALBP-deficient mice could be caused by a deficit either in cone phototransduction or in cone-to-bipolar cell synaptic transmission. To distinguish between the 2 possibilities, we determined whether cone phototransduction was affected directly by the deletion of CRALBP by performing ex vivo

Figure 2. Deletion of CRALBP reduces transretinal cone-response amplitude and sensitivity. (A) Representative transretinal cone responses from control (left panel) and *Rlbp1*^{-/-} (right panel) retinas. Test flash intensities increased from 23 photons/ μm^2 to 1.40×10^6 photons/ μm^2 in steps of 0.5 log units. For both panels, the flash intensity producing the response shown in red was 1.39×10^4 photons/ μm^2 . (B) Ensemble-averaged absolute and normalized (inset) cone intensity-response curves for control ($n = 13$) and *Rlbp1*^{-/-} ($n = 13$) retinas. (C) Ensemble-averaged normalized cone dim flash responses from control ($n = 12$) and *Rlbp1*^{-/-} ($n = 13$) retinas. (D) Ensemble-averaged dim flash responses, r , from control ($n = 13$) and *Rlbp1*^{-/-} ($n = 11$) cones normalized to the maximal response, r_{max} , and to flash intensity and with matched rising slopes to determine the change in phototransduction amplification. Results are shown as the mean \pm SEM.

recordings from isolated retina. This technique allowed us to pharmacologically block synaptic transmission (see Methods) and isolate the cone (a-wave) response. We used a 505-nm LED flash light to stimulate the M-cones in these recordings. Similar to the in vivo ERG b-wave results above, the ex vivo transretinal responses from *Rlbp1*^{-/-} cones were smaller than those from control cones, with a greater than 50% ($P < 0.05$) decrease in maximal amplitude (Figure 2, A and B). Indicative of their reduced sensitivity, the responses of *Rlbp1*^{-/-} M-cones could not be saturated, even at the maximal possible light intensity of our system (Figure 2B). The analysis of their corresponding intensity-response functions showed a 20-fold lower sensitivity (higher $I_{1/2}$) compared with that in control cones (Figure 2B, inset). The absence of CRALBP also resulted in a somewhat accelerated cone response inactivation (Figure 2C). In addition, consistent with their reduced light sensitivity, CRALBP-deficient cones had a 9-fold smaller phototransduction amplification compared with that in control cones (Figure 2D), revealed by the corresponding scaling factor required to match the rising slopes of the fractional dim flash responses to 103 photons/ μm^2 for control cones and 1,387 photons/ μm^2 for *Rlbp1*^{-/-} cones. Taken together, these results demonstrate that deletion of CRALBP in mice leads to severe desensitization and altered cone phototransduction in dark-adapted M-cones, which in turn produces a desensitized cone b-wave and suppressed cone-mediated vision.

Deletion of CRALBP severely impairs mammalian cone dark adaptation. We next sought to determine the effect of CRALBP deletion on RPE and retina visual cycles in the context of cone dark adaptation. First, we determined the overall effect of CRALBP deletion on

cone dark adaptation. Using in vivo ERG recordings, we examined the cone b-wave sensitivity recovery of control and *Rlbp1*^{-/-} mice following exposure to a brief bright-green light estimated to photoactivate (bleach) 90% of the M-cone visual pigment (see Methods for details). As expected, cone b-wave sensitivity in the control mice underwent robust recovery following the bleaching and returned within 50 minutes to an estimated 50% of the pre-bleaching level (Figure 3A, black squares). An incomplete photoreceptor dark adaptation after bleaching, as detected in ERG recordings of WT mice, is not unusual (6) and is most likely caused by the general anesthetics (25). In striking contrast to the ERG response recovery in control mice, M-cones in *Rlbp1*^{-/-} mice recovered only a slight fraction of their sensitivity following an identical bleaching (Figure 3A, red circles). Thus, cone dark adaptation in vivo, driven through the combined action of the RPE and Müller cell visual cycles, was severely compromised by the deletion of CRALBP. Notably, the effect of CRALBP deletion on the recovery of cone sensitivity was more pronounced than the previously reported delay in recovery of cone b-wave-response amplitudes (22).

Next, to determine the specific effect of CRALBP deletion on the Müller cell visual cycle, we performed cone dark-adaptation experiments in retina dissected free of RPE, in which cone pigment regeneration can be driven only by the retinal visual cycle. After an initial greater than 100-fold desensitization caused by the bleaching, within seconds, cones in both control and *Rlbp1*^{-/-} retinas showed a rapid initial increase in sensitivity (Figure 3B). This partial recovery, which was most likely due to inactivation of the phototransduction cascade following the bleaching, was comparable in the 2 mouse strains. However, the *Rlbp1*^{-/-} cone sensitivity failed to recover further during the 12 minutes of post-bleach recordings, while control cones recovered to within 5-fold of their pre-bleaching level (Figure 3B). We conclude that deletion of CRALBP has a dramatic effect on the ability of the retinal visual cycle to promote mouse cone dark adaptation. Taken together, these results demonstrate that CRALBP plays a role in both the RPE and retinal visual cycles and that its deletion severely impairs the ability of both pathways to promote mammalian cone dark adaptation.

Dark rearing of CRALBP-deficient mice restores cone function but not cone dark adaptation. It is believed that the role of CRALBP in both the RPE and retinal visual cycles is to accelerate the production of 11-*cis* retinoid (1). We hypothesized that in the absence of CRALBP, both visual cycles would still remain functional but would fail to provide sufficient chromophore for sustaining normal

Figure 3. The deletion of CRALBP suppresses cone dark adaptation. (A) Normalized cone b-wave sensitivity (b-wave S_f / b-wave S_f^{DA}) from in vivo ERG recordings during dark adaptation following 90% pigment bleaching at $t = 0$ for control ($n = 10$) and $Rlbp1^{-/-}$ ($n = 10$) mice. (B) Cone sensitivity, S_f , normalized to its dark-adapted value, S_f^{DA} , from transretinal recordings during dark adaptation following 90% pigment bleaching at $t = 0$ for control ($n = 9$) and $Rlbp1^{-/-}$ ($n = 10$) isolated retinæ. Results represent the mean \pm SEM.

cone function in 12-hour light/12-hour dark cyclic conditions. To test this idea, we first attempted to restore cone function in $Rlbp1^{-/-}$ mice by supplying them with exogenous chromophore in order to regenerate any free cone opsin into visual pigment. However, the application of either 9-*cis* retinal in vivo (Figure 4A) or 11-*cis* retinal ex vivo (Figure 4B) failed to rescue M-cone sensitivity. In contrast, treatment of chromophore-deficient $Rpe65^{-/-}$ retinæ with exogenous 11-*cis* retinal ex vivo and application of 9-*cis* retinal to $Rpe65^{-/-}$ mice in vivo resulted in a robust increase in rod sensitivity and maximal response (data not shown), as previously reported (26, 27). These results demonstrate that free opsin is not present

in $Rlbp1^{-/-}$ cones in detectable amounts and therefore is not the cause for the reduced sensitivity and response amplitude of cones in CRALBP-deficient mice.

We next examined whether the suppressed M-cone function in CRALBP-knockout mice is caused by a long-term chromophore deficiency. We raised $Rlbp1^{-/-}$ newborn mice in near-complete darkness to substantially slow down the consumption of chromophore in their eyes and lower the demand for recycled chromophore by the cones. It was recently shown that raising mice in complete darkness leads to an eventual decline in cone-to-bipolar cell synaptic transmission (28). However, the occasional

Figure 4. Dark rearing, but not acute treatment with exogenous chromophore, rescues CRALBP-deficient cone sensitivity. (A) Normalized in vivo ERG cone b-wave intensity-response curves for untreated control (replotted from Figure 2B inset) and 9-*cis* retinal-treated ($n = 6$) $Rlbp1^{-/-}$ mice. (B) Normalized transretinal cone intensity-response curves for control (black, $n = 6$) and $Rlbp1^{-/-}$ (red, $n = 6$) retinæ in control solution (filled symbols; replotted from Figure 3B inset) and after treatment with exogenous 11-*cis* retinal (open symbols, $n = 6$). 9cRal, 9-*cis* retinal; 11cRal, 11-*cis* retinal. (C) Cone b-wave intensity-response curves from in vivo ERG recordings of control mice raised in cyclic light (black squares, $n = 14$) or in darkness (white squares, $n = 10$). (D) Cone b-wave intensity-response curves from in vivo ERG recordings of control (black squares; replotted from Figure 1B) and $Rlbp1^{-/-}$ mice raised in cyclic light (red filled circles; replotted from Figure 1B) and $Rlbp1^{-/-}$ mice raised in darkness (open red circles, $n = 10$). Insets in C and D show the corresponding normalized intensity-response curves. (E) Normalized cone b-wave sensitivity (b-wave S_f / b-wave S_f^{DA}) from in vivo ERG recordings during dark adaptation following 90% pigment bleaching at $t = 0$ for control (black squares) and $Rlbp1^{-/-}$ mice raised in cyclic light (filled red circles; replotted from Figure 4A) and for $Rlbp1^{-/-}$ mice raised in darkness (open red circles, $n = 10$). Results represent the mean \pm SEM.

Figure 5. Deletion of CRALBP affects the localization of M-opsin and number of cones expressing M-opsin. Antibody staining of retinal frozen sections from *Rlbp1*^{-/-} and control mice for (A) M-opsin and (B) S-opsin. Representative images are shown. At least 3 retinæ per condition were examined. Scale bars: 25 μ m. COS, cone outer segment; ONL, outer nuclear layer; OPL, outer plexiform layer. For clarity, the DAPI channel is not shown. (C) Quantification of whole-mount M-opsin antibody staining ($n = 4$ retinæ per condition). * $P < 0.05$, ** $P < 0.01$ by unpaired 2-tailed Student's t test. (D) Quantification of whole-mount S-opsin antibody staining ($n = 3$ retinæ per condition). D, dorsal; T, temporal; N, nasal; V, ventral. Young, 6- to 7-week-old mice; Old, 3- to 6-month-old mice. Results represent the mean \pm SEM.

brief exposure to room light during routine animal care was sufficient to maintain normal cone function in our control mice and resulted in only a slight increase in the maximal amplitude of their in vivo ERG b-wave response (Figure 4C). Importantly, the photopic b-wave sensitivity of control mice, as measured from their normalized intensity-response curve, was unchanged by the dark rearing (Figure 4C, inset). In contrast, raising *Rlbp1*^{-/-} mice in darkness not only restored cone b-wave maximal response (Figure 4D), but also boosted cone sensitivity levels to those of control cones (Figure 4D, inset). However, a subsequent exposure to bleaching light unmasked the deficiency in cone pigment regeneration, as the dark adaptation in CRALBP-deficient mice was identical for animals raised in darkness and in cyclic light (Figure 4E). Together, these results demonstrate that the dark rearing of *Rlbp1*^{-/-} mice slows down the consumption of chromo-

phore enough to preserve cone function. However, dark rearing alone does not address the underlying deficit in the RPE and/or retinal visual cycles.

Deletion of CRALBP induces M-opsin mislocalization and loss of M-cones. What is the molecular mechanism underlying the functional deterioration in CRALBP-deficient cones? Based on the physiological results above, we hypothesized that CRALBP was required for proper localization of opsin protein. To test this hypothesis, we stained frozen sections from *Rlbp1*^{-/-} and control retinæ with cone opsin antibodies. Whereas M-opsin was localized to the cone outer segment of the control retinæ as expected, we observed striking mislocalization of M-opsin to the cone cell bodies, axons, and pedicles of young (6-week-old) and old (4- to 6-month-old) *Rlbp1*^{-/-} mice raised conventionally in cyclic light-dark conditions. Intriguingly, dark rearing of *Rlbp1*^{-/-} mice

Figure 6. AAV-mediated delivery of CRALBP to Müller cells or RPE cells. Antibody staining shows expression pattern of CRALBP in (A) control retina, (B) *Rlbp1*^{-/-} retina, (C) Müller cells of *Rlbp1*^{-/-} retina after intravitreal injection with an AAV construct targeted for Müller cells shH10-scCAG-RLBP1, and (D) RPE of *Rlbp1*^{-/-} retina after intravitreal injection with an AAV construct targeted for RPE 7m8-scVMD2-RLBP1. Scale bars: 50 μ m. INL, inner nuclear layer; GCL, ganglion cell layer. Widespread infection across the retina was achieved for both constructs, as seen in tiled images for (E) shH10-scCAG-RLBP1 and (F) 7m8-scVMD2-RLBP1. Red channel, anti-CRALBP; blue channel, DAPI. Scale bar: 200 μ m.

appeared to ameliorate M-opsin mislocalization to some extent (Figure 5A), consistent with the physiology results above. In contrast to M-opsin, S-opsin was appropriately localized to the cone outer segments in the retinæ of both *Rlbp1*^{-/-} and control mice (Figure 5B). We also wondered whether the M-opsin mislocalization in *Rlbp1*^{-/-} retinæ was correlated with M-cone numbers. Quantification of whole-mount antibody staining revealed a lower density of M-opsin-expressing cones in the dorsal retinæ of *Rlbp1*^{-/-} mice compared with dorsal retinæ in age-matched controls (Figure 5C), whereas the density of S-opsin-expressing cones was not affected (Figure 5D). Thus, the deletion of CRALBP resulted in both mislocalization of M-opsin and M-cone loss. However, overall, the cone density in *Rlbp1*^{-/-} retinæ did not change markedly with age, suggesting that the observed age-dependent decline in cone function was caused by progressive deterioration in the light responses of individual M-cones.

The retinal visual cycle is essential for cone function. In the above results, we demonstrated that CRALBP was crucial for maintaining normal M-cone function in a cyclic light environment and for proper cone dark adaptation. However, because in these experiments CRALBP was absent in both RPE and Müller cells, we were not able to determine the relative contribution of each visual cycle to maintaining normal cone function. To address this question, we used 2 separate AAV vectors to express CRALBP specifically in either RPE or Müller cells of adult *Rlbp1*^{-/-} mice (see Methods for details). First, we verified that CRALBP was delivered via intravitreal AAV injection to the RPE (via the RPE-specific AAV construct 7m8-scVMD2-RLBP1) or to the Müller cells (via the Müller cell-specific AAV construct shH10-scCAG-RLBP1) in *Rlbp1*^{-/-} retinæ. As previously shown (22), antibody staining revealed robust CRALBP expression in the RPE and Müller cells of WT mice (Figure 6A) and its complete absence in *Rlbp1*^{-/-} eyes (Figure 6B). Notably, immunohistochemistry revealed expression of CRALBP

specifically in the targeted cell type for both AAV constructs (Figure 6, C and D). Moreover, the extent of intravitreal AAV infection appeared to be widespread, as demonstrated by the CRALBP expression in the targeted cell type along the length of the retina (Figure 6, E and F).

We then examined how the rescue of each visual cycle affected the dark-adapted function of M-cones as well as their ability to recover light sensitivity rapidly following a bleaching. The transretinal recordings revealed that dark-adapted cone sensitivity in Müller cell CRALBP-expressing *Rlbp1*^{-/-} mice was improved by approximately 10-fold (Figure 7A) and that amplification of cone phototransduction was enhanced by 5.8-fold compared with controls (Figure 7B). In contrast, dark-adapted cone responses from RPE cell CRALBP-expressing *Rlbp1*^{-/-} mice were indistinguishable from those of their AAV-GFP-injected littermates (Figure 7, A and B). This result demonstrates that expression of CRALBP in Müller cells is required for the normal function of dark-adapted M-cones. The dim flash-response kinetics, cone maximal response, and cone b-wave maximal response were not affected by either RPE or Müller cell expression of CRALBP (data not shown), indicating an incomplete rescue of cone function. We also note that AAV-mediated CRALBP delivery to either RPE or Müller cells failed to correct the M-opsin mislocalization defect (data not shown). Notably, *in vivo* cone dark adaptation was markedly improved by the AAV-mediated CRALBP rescue of either visual cycle with indistinguishable time courses (Figure 7C). In contrast, only the expression of CRALBP in Müller cells resulted in the rescue of cone dark adaptation in the isolated RPE-free retina, whereas expression of CRALBP in RPE had no effect on cone dark adaptation under these conditions (Figure 7D). Together, these results demonstrate the role of the retinal visual cycle in supporting mammalian M-cone function and indicate that CRALBP in Müller cells plays a key role in this pathway.

Figure 7. AAV-driven expression of CRALBP in Müller cells rescues the sensitivity and dark adaptation of CRALBP-deficient cones. (A) Ensemble-averaged transretinal cone intensity-response curves for *Rbpl1*^{-/-} mice injected with AAV driving expression of GFP in RPE or Müller cells (black squares, *n* = 4), CRALBP in Müller cells (red circles, *n* = 5), and CRALBP in RPE cells (green diamonds, *n* = 3). (B) Transretinal dim flash responses of *Rbpl1*^{-/-} mice showing the relative amplification for AAV-driven control GFP (black, *n* = 4), Müller cell-specific CRALBP (red, *n* = 5), and RPE-specific CRALBP (green, *n* = 3) expression. (C) In vivo ERG recordings of cone b-wave dark adaptation (b-wave S_f/S_f^{DA}) after a 90% bleaching in *Rbpl1*^{-/-} mice with AAV-driven expression of control GFP (black, *n* = 11), Müller cell-specific CRALBP (red, *n* = 12), and RPE-specific CRALBP (green, *n* = 8). (D) Transretinal recordings of cone dark adaptation (S_f/S_f^{DA}) after a 90% bleaching of *Rbpl1*^{-/-} retinæ with AAV-driven expression of control GFP (black, *n* = 4), Müller cell-specific CRALBP (red, *n* = 5), and RPE-specific CRALBP (green, *n* = 3). Results represent the mean \pm SEM.

Deletion of CRALBP affects the pupillary light reflex. Besides rods and cones, another cell type in the retina that requires chromophore for its function is the intrinsically photosensitive retinal ganglion cell (ipRGC) (29). CRALBP in Müller cells was recently proposed to facilitate the supply of 11-*cis* retinal to ipRGCs (30). We investigated this possibility by evaluating the effect of CRALBP deletion on light-driven pupil constriction. Rods in both control and *Rbpl1*^{-/-} mice do not respond to light due to the absence of GNAT1, and their pupillary light reflex is therefore mediated by the 2 remaining light-sensitive cell types in the retina: cones and ipRGCs (31). In melanopsin-knockout animals that lack melanopsin phototransduction but maintain normal cone function, there is a clear reduction in the magnitude of the pupillary light reflex, but only at high light intensities (32). To determine whether melanopsin phototransduction is affected in *Rbpl1*^{-/-} mice, we exposed 1 eye to light and measured pupil constriction in the contralateral eye (Figure 8A). This enabled us to evaluate the overall sensitivity of the pupillary light reflex. Two-way ANOVA analysis showed an overall significant difference ($P < 0.001$) between the pupil constriction intensity-response curves of control and *Rbpl1*^{-/-} mice. Further 1-way ANOVA statistical analysis followed by Bonferroni's correction on the *P* values at each intensity revealed a significantly higher ($P < 0.05$) threshold for pupil constriction in *Rbpl1*^{-/-} mice compared with that in controls (Figure 8B). The light intensity required to reach 50% effective constriction (EC_{50}) was also slightly higher in CRALBP-deficient mice compared with that in controls, but the difference was not statistically significant (Figure 8C). The maximal pupil constriction in bright light of *Rbpl1*^{-/-} mice was comparable to that of controls, suggesting that the function of ipRGCs is largely unaffected by the deletion of CRALBP (32). In contrast, the maximal pupillary light reflex of *Rpe65*^{-/-} mice, in which all photoreceptor function is severely suppressed due to

a lack of chromophore (33), was dramatically reduced (Figure 8, A and B). This analysis suggests that the pupillary light reflex is overall different in *Rbpl1*^{-/-} mice, with the difference restricted to relatively dim light levels, in which the pupil response is primarily driven by cone signals. The response at higher light intensities, which is dominated by the ipRGC signals, was not affected by the deletion of CRALBP. Together, these results indicate that CRALBP is not required for the delivery of chromophore to ipRGCs or for the regeneration of melanopsin and that the decreased sensitivity of the pupillary light reflex in *Rbpl1*^{-/-} mice is most likely caused by suppressed cone function. However, a conclusive determination of this issue would require the generation of triple-knockout animals that lack both rod and cone phototransduction pathways in addition to a lack of the *Rbpl1* gene.

Discussion

Molecular evidence for the function of a mammalian retinal visual cycle. The idea of a second, cone-specific visual cycle was first put forth in the 1970s (34) and has been gaining acceptance and experimental support in recent years (3, 4, 35). This pathway was proposed to involve the conversion of spent all-*trans* retinol, released from cones, back into 11-*cis* retinol in the retinal Müller cells (3). Indeed, it was shown recently that the retina promotes pigment regeneration and dark adaptation in cones independently of the RPE, and that pharmacological ablation of Müller cells blocks this process (5). Recent biochemical studies have identified putative retinoid isomerase (7) and ester synthase activities (8) in Müller cells consistent with a retinal visual cycle. However, the molecular mechanism involved in the trafficking and recycling of chromophore still remains largely unknown, and skepticism still remains, partly due to the lack of experimental evidence for the involvement of any of the putative molecular players in this path-

Figure 8. Deletion of CRALBP reduces the threshold of the pupillary light reflex. (A) Comparison of pupil size in darkness and in the light (~ 14 log photons/cm²/s) in control, *Rlbp1*^{-/-}, and *Rpe65*^{-/-} (*Gnat1*^{-/-}) negative control mice. (B) Averaged intensity-response curves for control ($n = 5$), *Rlbp1*^{-/-} ($n = 5$), and *Rpe65*^{-/-} ($n = 4$) mice. A significant difference was observed at threshold ($*P < 0.05$) between *Rlbp1*^{-/-} and control mice by 2-way ANOVA followed by Bonferroni's post test. Results represent the mean \pm SEM. (C) Intensity required to reach EC₅₀ in control and *Rlbp1*^{-/-} mice. $P = 0.10$, NS, by 2-tailed unpaired Student's *t* test.

way in actually controlling the function of cones. Here, we settle this question by demonstrating that the deletion of CRALBP in Müller cells prevents this pathway from promoting dark adaptation in mouse cones. Our results also reveal a previously unappreciated role of the retinal visual cycle in the long-term maintenance of normal mammalian cone function.

The role of CRALBP in the retinal visual cycle. We found that deletion of CRALBP in mice resulted in a dramatic suppression of cone dark adaptation both in vivo, when driven by the combined action of the RPE and retinal visual cycles (Figure 3A), and ex vivo, when driven only by the retinal visual cycle (Figure 3B). Therefore, suppression of the RPE visual cycle by deletion of CRALBP not only affects the rods, as previously shown by Saari et al. (22), but also compromises the ability of the RPE to drive the dark adaptation of cones. More important, our results also clearly demonstrate that CRALBP in Müller cells plays a similar role in the retinal visual cycle to promote cone dark adaptation.

What is the mechanism of CRALBP function in the retinal visual cycle? The rescue of cone function in dark-reared *Rlbp1*^{-/-} mice indicates that deletion of CRALBP does not block the function of the retinal visual cycle; rather, CRALBP likely regulates its efficiency or kinetics. In RPE, CRALBP interacts with the isomerohydrolase to carry 11-*cis* retinol and facilitate its oxidation to 11-*cis* retinal (36). A recent study suggests that in vitro CRALBP closely interacts with DES1, the proposed retinoid isomerase in Müller cells (7). Therefore, it is possible that CRALBP takes up 11-*cis* retinol from DES1 and facilitates the reisomerization of chromophore by the retinal visual cycle. CRALBP also facilitates the release of chromophore from RPE cells and its subsequent uptake by photoreceptors (37, 38). Thus, a second possibility is that CRALBP plays a similar role in Müller cells and accelerates the flow of chromophore to cones.

The influence of chromophore deficiency on cone function. Rods in CRALBP-deficient mice have normal sensitivity and maximal response after overnight dark adaptation (22). In striking contrast, dark-adapted cones in CRALBP-deficient mice have significantly reduced response amplitude and 20-fold lower sensitivity

(Figures 1 and 2). Notably, this suppressed cone function can be rescued by raising the animals in darkness (Figure 4). This result indicates that unlike the other widely studied chromophore-binding protein IRBP (39, 40), CRALBP is not required for the normal development and survival of cones. Instead, the preservation of normal cone function in dark-reared *Rlbp1*^{-/-} mice suggests that the cone phenotype is caused by inadequate chromophore supply. One possibility is that the delayed recycling of chromophore in the absence of CRALBP leads to chronic chromophore deficiency, so that even after overnight dark adaptation of these mice, the pigment content of their cones is still not fully restored. However, consid-

ering that CRALBP-deficient rod responses are normal after 18 hours of dark adaptation (22), it is unlikely that only cones would be affected by such incomplete dark adaptation. Indeed, our observation that application of exogenous chromophore failed to rescue cone function (Figure 4) rules out this possibility.

An alternative hypothesis is that the chronic deficiency of chromophore affects cone opsin levels. Evidence for this notion comes from studies of a key enzyme in the RPE visual cycle, RPE65. In contrast to the slowed-down RPE visual cycle in *Rlbp1*^{-/-} mice, *Rpe65*^{-/-} mice lack this pathway completely and are unable to supply chromophore to their photoreceptors (41). This results in mislocalization of cone opsin and very rapid degeneration of the cones (42, 43), both of which are attributed to chromophore deficiency (42, 44). Consistent with the role of chromophore in supporting cone opsin folding and expression, a recent study demonstrated that proper cone opsin expression requires sufficient chromophore supply to the endoplasmic reticulum (45). In addition, 11-*cis* retinal in the inner segment of cones also appears to facilitate the transport of several phototransduction proteins to the cone outer segments (46). Thus, the deterioration of M-cone function that we observed in *Rlbp1*^{-/-} mice is likely a direct result of the chromophore deficiency caused by impairment of the retinal visual cycle. Notably, we found that S-cone opsin localization and expression were not affected in *Rlbp1*^{-/-} mice (Figure 5, B and D), indicating that apo S-opsin might be more stable than its M-opsin counterpart. It is intriguing in this context that mouse M-cones are more susceptible to age-dependent degeneration than are S-cones (47), suggesting that cone opsin stability might play a role in age-dependent cone degeneration. Regardless of the mechanism affecting the loss of cone function in *Rlbp1*^{-/-} mice, the rescued cone function in animals raised in darkness suggests that minimizing light exposure might be a simple and effective approach for protecting cones from degeneration and preventing photopic vision loss in patients with CRALBP-based visual disorders.

The contribution of 2 visual cycles to cone function. By selectively rescuing either the RPE or Müller cell visual cycle using AAV-RLBP1 in *Rlbp1*^{-/-} mice, we were able to identify the contribu-

tion of each visual cycle to supporting normal cone sensitivity and dark adaptation. Our finding that only rescue of the retinal visual cycle, but not the RPE visual cycle, restores normal sensitivity of dark-adapted *Rlbp1*^{-/-} cones (Figure 7) reveals a previously unappreciated function of the retinal visual cycle and demonstrates that this pathway plays a crucial role in maintaining long-term cone function. One interesting unexplored possibility emerging from these results is that age-dependent decline in the efficiency of the Müller cell visual cycle contributes to the gradual loss of cone function and is linked to age-related cone visual disorders in patients. Thus, genetic or pharmacological treatments aimed at boosting the retinal visual cycle might have therapeutic benefit for age-dependent cone visual loss.

It has been suggested that cone dark adaptation is biphasic, with an initial fast recovery dominated by the retinal visual cycle and a slow subsequent recovery contributed by the RPE visual cycle (6). However, we found that the rescue of either of the 2 visual cycles in *Rlbp1*^{-/-} mice results in cone dark adaptation in vivo with indistinguishable kinetics (Figure 7C). It is not clear at the moment whether this reflects a more complex interplay between the contributions of the 2 visual cycles than was previously appreciated, or a developmental compensatory modulation of 1 pathway in the absence of the other. Interestingly, neither of the rescues of the 2 visual cycles restored the maximal cone response, suggesting reduced cone number or phototransduction capacity. One possibility is that both visual cycles are required for normal cone function. Alternatively, it is possible that the loss of cone function in *Rlbp1*^{-/-} mice is caused by chromophore deficiency at an early stage of development and therefore could not be rescued by AAV injections in adult animals. While the 2 hypotheses are not mutually exclusive, our aging experiments on *Rlbp1*^{-/-} mice (Figure 1) support the latter. Future studies with animals of different ages should resolve these questions and provide invaluable information about the therapeutic potential of such treatments. Notably, we were able to achieve selective and highly efficient CRALBP expression in Müller cells and even in the RPE (Figure 6F) with an intravitreal AAV injection.

Methods

Animals. CRALBP-deficient mice (22) were provided by John Saari (University of Washington, Seattle, Washington, USA). To facilitate cone recordings, CRALBP-knockout mice were crossed with rod transducin α -knockout mice (*Gnat1*^{-/-}) (23) obtained from Janis Lem (Tufts University, Boston, Massachusetts, USA) to eliminate rod responses. The role of CRALBP in cone function and morphology was then determined by comparing adult (6 weeks to 6 months of age) control (*Gnat1*^{-/-}) and *Rlbp1*^{-/-} (CRALBP-deficient *Gnat1*^{-/-}) mice. All mice used in this study were confirmed to be free of the *rd8* mutation (48). For dark-rearing experiments, newborn mice were transferred to a light-proof cabinet and briefly exposed to ambient light only once a week during cage changing. All other mice were raised in a 60 Lux 12-hour light/12-hour dark cycle. Animals were dark adapted for 18 hours before electrophysiological recordings and at least 30 minutes prior to pupillary light reflex tests. The animals used for the optometry tests were light adapted before the experiment. In addition, *Rpe65*^{-/-} (*Gnat1*^{+/+}) mice were used as control animals for pupillary light reflex and exogenous chromophore treatment experiments.

Photopic vision measured from optomotor responses. The threshold of contrast sensitivity was measured with a commercially available OptoMotry System (CerebralMechanics) as previously described (6). The intensity of the background light of the system was controlled with a custom-made cylinder of neutral-density filter film, wrapped around the mouse stand. The contrast-sensitivity threshold at a 0.128 cycles/degree grating spatial frequency was measured by an automated computer program when mice failed to provide optomotor responses. The tests started from brightest (1.84 log cd \times s/m²) to dimmest (-3.56 log cd \times s/m²) background light intensity. Intriguingly, we observed that 2 of the tested CRALBP-deficient *Gnat1*^{-/-} mice (*Rlbp1*^{-/-}) did not respond normally to the moving bar in the test and instead rotated their head in the direction opposite to the moving bar. Therefore, we excluded the results from these 2 mice from our analysis.

Electrophysiology. In vivo ERG recordings were performed with a commercial LKC system (LKC Technologies) as previously described (6). The dark-adapted animals were anesthetized with ketamine (100 mg/kg) and xylazine (20 mg/kg), and their pupils were dilated with atropine sulfate eye drops. A mouse was placed onto a 37°C heating pad, and electrodes were connected to its cornea to amplify electrical signals generated by the retina. A reference electrode was connected to beneath the skin at the scalp between the eyes. The animal was allowed to stabilize in darkness for 15 minutes before the recordings were started. Test flashes of increasing intensity (530-nm LED up to a 25 cd \times s/m² limit and white Xenon flash for higher intensities) were delivered by the Ganzfeld sphere, and the ERG signals were recorded to obtain the intensity-response curves. To test the dark-adaptation kinetics, bright-green LED light (520 nm) was used to bleach an estimated 90% of the photopigments in 30 seconds. Then the cone sensitivity was recorded at pre-set time intervals until 52 minutes after photobleaching. The cone b-wave flash sensitivity was normalized to the pre-bleaching value to determine the sensitivity recovery curve. For exogenous chromophore application experiments, 300 μ g 9-*cis* retinal was dissolved in 200 μ l NaCl/BSA solution (with 10% ethanol) and administered by i.p. injection. The treated animals were dark adapted overnight prior to in vivo ERG recordings.

Transretinal recordings were performed with isolated mouse retina as previously described (49, 50). The isolated retina was carefully mounted on a custom-made chamber for transretinal voltage recordings (51). The retina was perfused with Locke's solution bubbled with O₂ and CO₂ and supplemented with 30 μ M DL-AP4 to block synaptic transmission. After setting up the recording chamber, the retina was allowed to stabilize for 15 minutes before any recording was done. The responses of cones to 1-ms-long 505-nm LED-generated test flashes of various intensities were amplified and recorded on a desktop computer with pClamp 10 software (Molecular Dynamics). Dim flash analysis was performed with amplitude responses below 30% of the maximal amplitude for each retina (52). For dark-adaptation tests, preprogrammed protocols were used to precisely monitor the fast recovery of cone sensitivity during the first 12 minutes following an estimated 90% photobleaching of the visual pigments. The cone sensitivity was normalized to the pre-bleaching level to generate the sensitivity recovery curve. For exogenous chromophore application experiments, 300 μ g 11-*cis* retinal was dissolved in 4 ml 0.01% ethanol Locke's solution, and an isolated retina was incubated with 0.5 to 1 ml of that solution for 1 hour in darkness. Cone responses from the treated retinæ were

then obtained using transretinal recordings. For all recordings, the sensitivity, S_p , was estimated from the ratio of the amplitude, r , of a flash response from the linear range (<30% of the saturated response, r_{max}) and the corresponding flash intensity.

Frozen sections. Eyes were fixed in 4% paraformaldehyde in PBS for 2 hours at room temperature, rinsed with PBS, and then cryoprotected in 30% sucrose. The lens was removed prior to embedding in Tissue-Tek OCT compound (Sakura). Frozen blocks were cryosectioned at a thickness of 12 to 14 μm . For immunohistochemical staining, sections were blocked for approximately 1 hour at room temperature, followed by overnight incubation at 4°C with primary antibody, except for anti-CRALBP, which was incubated for 2 hours at room temperature. The following primary antibodies were used: rabbit anti-red/green cone opsin (AB5405; EMD Millipore) at 1:600; rabbit anti-blue cone opsin (AB5407; EMD Millipore) at 1:200; and rabbit anti-CRALBP (UW55 polyclonal antibody isolated from rabbits immunized with human recombinant CRALBP; a gift of John Saari, University of Washington; refs. 22, 53) at 1:200. The following fluorescently labeled secondary antibodies were used, respectively: Alexa Fluor 555 donkey anti-rabbit (A-31572; Molecular Probes) at 1:800; Alexa Fluor 488 donkey anti-rabbit (A-21206; Molecular Probes) at 1:500; and Alexa Fluor 555 donkey anti-rabbit (A-31572; Molecular Probes) at 1:800. Secondary antibodies were applied for 30 minutes at room temperature, followed by DAPI staining, application of VECTASHIELD (Vector Labs), and coverslipping. The following blocking solutions were used: 0.1% Triton X-100 and 5% normal donkey serum in PBS for staining of opsins, and 0.5% Triton X-100 and 2% normal donkey serum in PBS for staining of CRALBP. Primary and secondary antibodies were diluted in blocking solution. Slides were stored at -20°C until imaging. Images were taken as multi-plane captures using an Olympus BX61WI microscope and a Hamamatsu ORCA-AG CCD camera and processed with MetaMorph software (Molecular Devices) and Adobe Photoshop, except for Figure 6, E and F, which were taken as single-plane captures using an Olympus BX51 microscope and an Olympus DP70 camera and processed with SlideBook software (Intelligent Imaging Innovations) and Adobe Photoshop.

Whole-mount immunostaining. Retinae were dissected in PBS with the lens intact, fixed for 30 minutes at room temperature with 4% paraformaldehyde in PBS, and rinsed with PBS prior to removal of the lens. Retinae were blocked for approximately 1 hour at room temperature, followed by overnight incubation at 4°C with the primary antibody. The following primary antibodies were used: rabbit anti-red/green cone opsin (AB5405; EMD Millipore) at 1:500 and goat anti-blue opsin (sc-14363; Santa Cruz Biotechnology Inc.) at 1:500. The following fluorescently labeled secondary antibodies were used, respectively: Alexa Fluor 555 donkey anti-rabbit (A-21206; Molecular Probes) at 1:800 and Alexa Fluor 488 donkey anti-goat (A-11055; Molecular Probes) at 1:800. Secondary antibodies were applied for 30 minutes at room temperature. A blocking solution consisting of 0.5% Triton X-100 and 2% normal donkey serum in PBS was used. Primary and secondary antibodies were diluted in blocking solution. Retinae were stored light-protected in PBS at 4°C until imaging, whereupon they were whole mounted with glass shards at the corners of the slide and coverslipped.

Cone quantification. Whole-mounted retinae were imaged as single-plane captures using a $\times 10$ objective lens with an Olympus BX51

microscope and an Olympus DP70 camera. Image files were annotated in Adobe Photoshop with dots to mark opsin staining. The dots were quantified using the “Analyze Particles” feature in ImageJ software (NIH). Quantification was conducted in 170 $\mu\text{m} \times 170 \mu\text{m}$ fields located in the dorsal, nasal, temporal, and ventral quadrants.

AAV vector preparation and injection. Four types of AAV vectors were used for the injection: shH10-scCAG-RLBP1 (expressing CRALBP in Müller cells, Müller-CRALBP); 7m8-scVMD2-RLBP1 (expressing CRALBP in RPE cells, RPE-CRALBP); shH10-scCAG-GFP (expressing GFP in Müller cells, GFP control); and 7m8-scVMD2-GFP (expressing GFP in RPE cells, GFP control). The Müller glia-specific viruses (shH10-scCAG-RLBP1/GFP) were constructed using a Müller glia-specific AAV serotype shH10 and the ubiquitous synthetic CAG promoter (54). The RPE-specific viruses (7m8-scVMD2-RLBP1/GFP) were built using a pan-retinally expressing AAV serotype 7m8 and the RPE-specific promoter *VMD2* (55, 56). To generate the scCAG-RLBP1 viral transfer plasmid, RLBP1 was reverse transcribed from purified WT mouse retina total mRNA. Then the GFP ORF of a self-complementary AAV vector expressing GFP under CAG promoter control was replaced with the *Rlbp1* cDNA using restriction enzymes. This plasmid was then further processed to generate the scVMD2-RLBP1 transfer plasmid through replacement of the CAG promoter with the PCR-purified *VMD2* promoter. The control scCAG-GFP and scVMD2-GFP viral plasmids were created using the same process without the replacement of the GFP ORF. For the generation of each virus, 293T cells at 80% confluence were cotransfected with the appropriate transfer plasmid, pHelper plasmid, and the AAV rep/cap plasmid (shH10 or 7m8) at a molar ratio of 1:1:1. At 72 hours after transfection, cells were collected, pelleted, resuspended in lysis buffer, freeze-thawed, and then treated with Benzonase. Cell debris was removed by centrifugation, and the supernatant was loaded onto an iodixanol gradient and subjected to ultracentrifugation. The 40% virus-containing iodixanol fraction was removed from the gradient, and the iodixanol was replaced via buffer exchange using Amicon Ultra-15 Centrifugal units in PBS. Titers were determined by quantitative PCR relative to a standard curve (57). An aliquot of 1 to 1.5 μl of the virus was injected into the vitreous of anesthetized 4-week-old mice using a Hamilton syringe. Animals were harvested 4–5 weeks after the injection for cone electrophysiology experiments and 8 weeks after the injection for immunohistochemistry.

Pupillary light reflex. All mice were awake and manually restrained while a 480-nm LED light was directed to 1 eye (the left eye). The light stimulus lasted for 30 seconds, after which the mouse was returned to its cage to dark adapt until the next light stimulus. Individual frames of the movie were taken from VLC Media Player. The images were analyzed in ImageJ. A comparison was made of the pupil area in darkness and after 30 seconds of light exposure to generate a ratio. For dose-response curves, the data were fitted with a variable-slope sigmoidal dose-response curve, with the top constrained to 1.0 and the bottom constrained between 0 and 0.1.

Statistics. Unless otherwise noted, a 2-tailed unpaired Student's *t* test was used to test for the significance of differences in the mean values of 2 sample groups. A *P* value of less than 0.05 was considered statistically significant.

Study approval. The care, maintenance, and treatment of the animals in this study followed protocols approved by the Washington University Animal Studies Committee.
